
Undergraduate Certificate in Advanced Combustion Engineering

High-Pressure Burner Design

Air-Fuel Ratio – mixing parameter. Related terms: stoichiometric ratio, equivalence ratio. The air-fuel ratio (AFR) is the mass ratio of air to fuel entering the combustion zone. Typical values range from 12:1 (rich) to 18:1 (lean) for natural gas. In high-pressure burners, precise AFR control influences flame stability, emissions, and thermal efficiency. Challenges include maintaining uniform mixing under turbulent, high-density conditions and compensating for pressure-induced changes in air density.

Air-Staging – combustion control. Related terms: staged combustion, NO_x reduction. Air-staging introduces a portion of the combustion air downstream of the primary flame, creating a fuel-rich zone followed by a lean zone. This technique reduces peak flame temperatures, thereby limiting thermal NO_x formation. Practical application: industrial furnaces operating at 10–30 bar. Main challenge: ensuring complete oxidation in the lean zone without excessive excess air, which can lower efficiency.

Back-Pressure – operating condition. Related terms: pressure drop, system resistance. Back-pressure refers to the resistance encountered by exhaust gases as they exit the burner and downstream equipment. High back-pressure can affect flame anchoring and increase the risk of flashback. Designers must size exhaust ducts and pressure relief devices to keep back-pressure within acceptable limits, typically below 0.5 bar for most high-pressure burners.

Blow-off Velocity – critical flow speed. Related terms: flame blow-off, extinguishment limit. This is the minimum gas velocity at which the flame detaches from the burner nozzle. At high pressures, blow-off velocity increases due to higher density and reduced diffusion rates. Example: a methane burner at 20 bar may have a blow-off velocity of 70 m s⁻¹. Designers must ensure that operating flow rates stay above this threshold to avoid flame extinction.

Burner Nozzle Geometry – design feature. Related terms: conical nozzle, sonic nozzle, expansion ratio. The shape and size of the nozzle dictate the velocity, pressure, and turbulence of the reactants. Convergent-divergent (CD) nozzles are common in high-pressure applications to accelerate the mixture to supersonic speeds before combustion. Challenges include machining tolerances, erosion resistance, and maintaining uniform flow distribution across the nozzle exit.

Burner Pressure Ratio – design metric. Related terms: inlet pressure, outlet pressure. The pressure ratio is the ratio of the pressure at the burner inlet to the pressure at the flame zone or exhaust. For high-pressure burners, typical ratios range from 1.2 to 1.8. A higher ratio can increase flame temperature but also raises the risk of flashback. Balancing this ratio is critical for safe, efficient operation.

Burner Staging – thermal management. Related terms: primary zone, secondary zone, tertiary zone. Burner staging divides the combustion process into distinct zones with controlled fuel and air distribution. In a three-stage high-pressure burner, the primary stage may operate fuel-rich for rapid ignition, the secondary stage introduces additional air for temperature rise, and the tertiary stage completes oxidation. Effective

staging reduces NO_x and improves fuel utilization, but requires precise flow control and robust instrumentation.

Combustion Instability – dynamic phenomenon. Related terms: acoustic coupling, thermo-acoustic oscillations. Instabilities arise when pressure waves interact with the heat release rate, leading to oscillations that can damage the burner. High-pressure burners are particularly susceptible due to the increased speed of sound and higher energy release. Mitigation strategies include damping liners, staged combustion, and active feedback control. Monitoring requires high-frequency pressure transducers and fast data acquisition.

Combustion Efficiency – performance indicator. Related terms: thermal efficiency, heat loss. Defined as the ratio of the heat actually transferred to the process fluid versus the heat released by fuel combustion. In high-pressure burners, efficiencies above 95 % are achievable with optimized mixing and minimal excess air. Losses stem from incomplete combustion, heat carried away by exhaust gases, and radiation from the flame. Accurate calorimetry and flue gas analysis are essential for assessment.

Combustion Noise – acoustic emission. Related terms: broadband noise, tonal noise. High-pressure burners generate audible noise due to turbulent mixing and pressure fluctuations. Excessive noise can indicate poor mixing or impending instability. Noise levels are measured in dB(A) and should be kept below 85 dB for occupational safety. Design solutions include acoustic liners, flow straighteners, and smoother nozzle contours.

Equivalence Ratio – fuel-richness metric. Related terms: ϕ , stoichiometric mixture. The equivalence ratio (ϕ) is the actual fuel-air ratio divided by the stoichiometric ratio. $\phi = 1$ denotes stoichiometric combustion; $\phi > 1$ is rich. In high-pressure burners, operating at $\phi \approx 0.9$ – 1.1 balances low NO_x with high efficiency. Controlling ϕ requires precise flow meters and real-time feedback loops.

Flame Temperature – thermal state. Related terms: adiabatic flame temperature, peak temperature. The flame temperature is the temperature of the reacting gases within the flame front. At 20 bar, the adiabatic flame temperature for methane can exceed 2100 K. Elevated temperatures increase NO_x formation and material stress. Cooling strategies include staged combustion, water injection, and diluent gases such as CO₂ or N₂.

Flame Speed – propagation rate. Related terms: laminar flame speed, turbulent flame speed. Laminar flame speed is the speed of a steady planar flame in a quiescent mixture; turbulent flame speed accounts for turbulence enhancement. High pressure reduces laminar flame speed due to increased density, but turbulent flame speed can be raised by increasing turbulence intensity. Accurate prediction uses empirical correlations or detailed chemical kinetics.

Flame Stabilization – anchoring technique. Related terms: pilot flame, recirculation zone. Flame stabilization ensures the flame remains attached to the burner under varying operating conditions. Common methods include a pilot flame, a vortex recirculation zone, or a bluff body. In high-pressure burners, recirculation is often achieved by shaping the nozzle to create a low-pressure wake where the flame can anchor. Improper stabilization can lead to blow-off or flashback.

Flashback – upstream flame propagation. Related terms: flame lift-off, back-flame. Flashback occurs when

the flame moves upstream into the premixing region, potentially damaging equipment. High pressure increases the risk because the flame speed can approach the flow velocity. Mitigation includes using flame arrestors, limiting the equivalence ratio, and designing the nozzle with sufficient expansion to keep flow velocity above flame speed.

Fuel-Rich Combustion – partial oxidation. Related terms: incomplete combustion, soot formation. Operating with a fuel-rich mixture ($\phi > 1$) reduces peak flame temperature, thereby lowering NO_x. However, excess fuel can lead to soot and carbon monoxide emissions. High-pressure burners may employ a rich primary zone followed by a lean secondary zone to complete oxidation while controlling emissions.

Fuel-Lean Combustion – low-temperature oxidation. Related terms: lean blow-off, excess air. Lean combustion (ϕ Fuel-Oxidizer Mixing – premixing process. Related terms: swirl, turbulence intensity. Effective mixing ensures uniform composition and temperature before ignition. Swirl generators, static mixers, and high-velocity jets are used to enhance mixing at high pressure where diffusion rates are slower. Poor mixing leads to hotspots, increased NO_x, and local flame extinction. Computational Fluid Dynamics (CFD) is commonly employed to optimize mixer designs.

Flue Gas Recirculation (FGR) – exhaust dilution. Related terms: EGR, dilution ratio. FGR routes a portion of the exhaust gases back into the combustion zone, lowering flame temperature and reducing NO_x. In high-pressure burners, FGR pressures match the inlet pressure, simplifying integration. Typical recirculation ratios range from 10 % to 30 %. Challenges include maintaining sufficient oxygen for complete combustion and avoiding excessive CO buildup.

Heat Transfer Coefficient – thermal exchange rate. Related terms: convection coefficient, radiative heat transfer. The coefficient quantifies how efficiently heat moves from the flame to surrounding surfaces. High-pressure burners often operate with enhanced convection due to higher gas densities, leading to coefficients of 150–300 W m⁻² K⁻¹. Accurate prediction requires accounting for turbulent flow, flame geometry, and surface roughness.

Ignition System – initiation device. Related terms: spark plug, pilot igniter, glow plug. The ignition system provides the energy needed to start combustion. In high-pressure burners, high-energy spark or pilot flames are common because the elevated pressure raises the ignition energy threshold. Reliability concerns include electrode erosion, fouling, and the need for redundancy in safety-critical installations.

Laminar Flame Speed – base propagation velocity. Related terms: S_L , temperature dependence. Laminar flame speed is a fundamental property of a fuel-air mixture, dependent on temperature, pressure, and composition. At 1 bar, methane-air mixtures have $S_L \approx 0.38 \text{ m s}^{-1}$; at 20 bar the speed drops to $\approx 0.20 \text{ m s}^{-1}$. Designers use S_L to estimate blow-off limits and to size mixing zones.

Lean Limit – minimum stable equivalence ratio. Related terms: blow-off limit, lean blow-off. The lean limit defines the lowest ϕ at which a stable flame can be maintained. It is a function of pressure, turbulence, and burner geometry. For high-pressure methane burners, the lean limit may be $\phi \approx 0.75$. Operating near this limit maximizes efficiency but demands precise flow control and robust monitoring.

Mass Flow Controller (MFC) – precision regulator. Related terms: flow meter, valve actuator. MFCs provide

accurate, repeatable control of fuel and air flow rates, essential for maintaining the desired AFR and equivalence ratio. High-pressure MFCs are rated up to 30 bar and often employ thermal or coriolis measurement principles. Calibration drift and pressure-induced nonlinearity are common challenges.

NO_x Formation – nitrogen oxides production. Related terms: thermal NO_x, prompt NO_x, fuel-bound NO_x. At high temperatures, atmospheric nitrogen reacts to form NO and NO₂. In high-pressure burners, NO_x is a primary pollutant concern. Mitigation methods include staged combustion, flue gas recirculation, water injection, and low-temperature combustion. Accurate prediction uses the extended Zeldovich mechanism and detailed kinetic models.

Oxidizer-Enriched Combustion – oxygen-boosted process. Related terms: oxy-fuel combustion, pure oxygen. Enriching the oxidizer with additional oxygen (or using pure O₂) raises flame temperature and reduces CO₂ volume, facilitating carbon capture. High-pressure burners can handle oxy-fuel streams because the pressure increase compensates for reduced volumetric flow. Challenges include material compatibility with high-temperature O₂ and the need for robust flame control to avoid flashback.

Pilot Flame – stabilizing flame. Related terms: ignition source, flame holder. A small, continuously burning flame that anchors the main combustion zone. In high-pressure burners, the pilot may be fueled with a richer mixture to ensure reliable ignition. The pilot flame must be positioned to create a recirculation zone without causing excessive heat load on the burner body. Failure of the pilot can lead to flame extinction and safety shutdown.

Pressure Drop – flow resistance loss. Related terms: ΔP , friction factor. Pressure drop across the burner and associated components determines required pump capacity and influences flow distribution. At high pressure, even small relative drops (e.g., 0.2 bar) can affect flame stability. Designers calculate ΔP using Darcy-Weisbach or empirical correlations, accounting for turbulence, surface roughness, and geometry.

Pressure Ratio – compressor-to-burner metric. Related terms: inlet pressure, outlet pressure. The pressure ratio is the ratio of the pressure supplied by the compressor to the pressure at the burner inlet. Ratios greater than 1.5 are common in industrial high-pressure burners. Higher ratios enable higher flame temperatures but increase mechanical stress and the risk of flashback. Proper selection ensures optimal performance while maintaining safety margins.

Premixed Burner – uniform mixture design. Related terms: diffusion burner, staged burner. Premixed burners combine fuel and oxidizer before ignition, producing a homogeneous mixture. They offer low emissions and high efficiency but are more prone to flashback at high pressure. Design strategies include using flame arrestors, limiting the equivalence ratio, and employing rapid mixing devices.

Recirculation Zone – vortex region. Related terms: swirl vortex, flame holder. A low-pressure zone created by geometry (e.g., backward-facing step) that draws hot combustion products back toward the flame base, stabilizing it. In high-pressure burners, the recirculation zone is critical for maintaining flame attachment under varying flow rates. Optimization involves adjusting step height, nozzle shape, and swirl number.

Safety Relief Valve – over-pressure device. Related terms: pressure relief, burst disc. The valve protects the burner system from excessive pressure by venting gas when a preset pressure is exceeded. For

high-pressure burners, relief valves are sized according to the maximum expected flow and must be compatible with the combustion gases to avoid corrosion. Regular testing and maintenance are required to ensure reliability.

Swirl Number – vorticity metric. Related terms: swirl intensity, vortex strength. Defined as the ratio of angular momentum to axial momentum of the flow. Swirl numbers between 0.5 and 1.5 are typical for high-pressure burners to create strong recirculation zones. Excessive swirl can cause flow separation and increased pressure loss, while insufficient swirl may lead to flame instability.

Thermal NO_x – high-temperature nitrogen oxide. Related terms: Zeldovich mechanism, temperature dependence. Thermal NO_x forms when nitrogen and oxygen react at temperatures above ~1800 K. High-pressure burners, due to elevated flame temperatures, are especially susceptible. Controlling peak temperature through staging, diluents, or water injection is the primary method of reduction.

Thermo-Acoustic Instability – oscillatory coupling. Related terms: acoustic resonance, heat release feedback. Occurs when pressure oscillations amplify heat release, which in turn reinforces the pressure waves, leading to destructive vibrations. High-pressure burners with large combustor volumes are prone to this phenomenon. Mitigation includes acoustic liners, adjusting fuel staging, and active control using modulators.

Triplet Burner – multiple-zone design. Related terms: multi-stage burner, three-stage combustion. A burner composed of three discrete combustion zones, each with independent fuel and air control. Used to achieve ultra-low NO_x (Water Injection – temperature moderating technique. Related terms: steam injection, liquid dilution. Introducing water or steam into the combustion zone absorbs heat, reducing peak flame temperature and consequently NO_x formation. In high-pressure burners, water can be injected at pressures matching the combustor to avoid flow disruption. Challenges include corrosion, scaling, and ensuring complete vaporization.

White-Flame – luminescent flame. Related terms: soot-free flame, radiant flame. A white-flame indicates low soot production, often achieved in well-mixed, lean, high-pressure burners. It is desirable for visual inspection and low radiative heat loss. However, maintaining a white-flame at high pressures requires precise control of equivalence ratio and adequate turbulence.

Zeldovich Mechanism – NO_x kinetic pathway. Related terms: thermal NO_x, reaction rate. The primary set of reactions describing the formation of NO from N₂ and O₂ at high temperatures. The rate is highly temperature dependent, following an Arrhenius expression with activation energy ~300 kJ mol⁻¹. Understanding this mechanism guides the design of temperature-limiting strategies such as staged combustion and diluent addition.

Acoustic Damping Liner – noise reduction feature. Related terms: muffler, liner material. A porous or perforated lining applied to the combustion chamber walls to absorb acoustic energy, reducing the amplitude of pressure oscillations that can cause thermo-acoustic instability. Materials include metal-filled ceramics and high-temperature foams. Effectiveness depends on liner thickness, porosity, and placement relative to pressure antinodes.

Adiabatic Flame Temperature – theoretical maximum temperature. Related terms: stoichiometric combustion, energy balance. Calculated assuming no heat loss, representing the upper limit of flame temperature for a given fuel-air mixture. For methane at 20 bar, the adiabatic temperature can exceed 2200 K. Real burners operate below this value due to heat transfer, radiation, and incomplete combustion.

Air-Fuel Mixing Time – pre-combustion interval. Related terms: residence time, turbulence time scale. The time required for fuel and air to achieve a homogeneous mixture before ignition. At high pressure, mixing time increases because diffusion rates are reduced; turbulent mixers are employed to shorten the interval to a few milliseconds. Insufficient mixing leads to localized rich pockets and higher emissions.

Back-Mixing – reverse flow phenomenon. Related terms: recirculation, vortex. Occurs when flow patterns cause a portion of the exhaust gases to re-enter the inlet region, potentially altering the mixture composition. In high-pressure burners, controlled back-mixing can be beneficial for flame stabilization, but excessive back-mixing may lead to flashback or increased emissions.

Blow-off Limit – maximum flow velocity before extinction. Related terms: blow-off velocity, flame extinction. The operational boundary where the flame can no longer remain anchored to the burner and is swept downstream. Determined by the balance of flame speed and flow velocity. High-pressure burners often have higher blow-off limits due to increased density, but also require higher fuel flow to sustain the flame.

Burner Head – primary combustion assembly. Related terms: nozzle block, flame holder. The burner head houses the fuel and air injection ports, mixing devices, and often the pilot flame. Materials must withstand high temperatures and pressures, commonly using Inconel or high-temperature stainless steels. Design considerations include thermal expansion, corrosion resistance, and ease of maintenance.

Combustion Chamber – reaction enclosure. Related terms: combustor, furnace. The volume where fuel-air mixing, ignition, and flame propagation occur. In high-pressure burners, the chamber is designed to minimize pressure losses while providing sufficient space for flame stabilization and heat exchange. Wall cooling, refractory lining, and structural reinforcement are critical to handle thermal stresses.

Diffusion Burner – non-premixed design. Related terms: diffusion flame, fuel-rich zone. Fuel and oxidizer are introduced separately, allowing mixing only by diffusion within the flame zone. Diffusion burners are less prone to flashback at high pressures but typically produce higher NO_x due to higher localized temperatures. Applications include large-scale industrial furnaces where simplicity outweighs emission concerns.

Flame Holding Device – anchoring component. Related terms: flame holder, pilot flame. Structures such as bluff bodies, recirculation plates, or vortex generators that create low-pressure zones to keep the flame attached. In high-pressure burners, the device must be robust against erosion and capable of withstanding high thermal loads. Proper sizing ensures flame stability without excessive pressure drop.

Flame Propagation Speed – combined laminar and turbulent rate. Related terms: flame speed, turbulent enhancement. The effective speed at which the flame front advances through the reactants, accounting for turbulence. Measured in m s^{-1} , values in high-pressure turbulent burners can reach $1\text{--}2 \text{ m s}^{-1}$. Accurate prediction requires turbulence models such as k- ϵ or LES coupled with flamelet approaches.

Fuel Flow Rate – mass delivery quantity. Related terms: volumetric flow, standard cubic meters per hour (SCMH). Determines the heat input and influences AFR. In high-pressure burners, flow rates are often expressed at operating pressure to avoid large correction factors. Precise metering is essential for maintaining desired equivalence ratio and preventing lean blow-off.

Heat Release Rate – energy output per unit time. Related terms: power density, combustion intensity. Calculated as the product of fuel mass flow, lower heating value, and combustion efficiency. High-pressure burners can achieve heat release rates of several megawatts, necessitating careful design to manage thermal stresses and avoid hot spots that could trigger flashback.

Ignition Delay – time between fuel injection and flame initiation. Related terms: spark timing, pilot ignition. At elevated pressures, ignition delay shortens because higher temperatures and densities increase reaction rates. Typical delays are on the order of milliseconds. Accurate timing is critical for sequential staging strategies where multiple zones ignite in a controlled sequence.

Laminar Flow – smooth, orderly flow regime. Related terms: Reynolds number, laminar-turbulent transition. In high-pressure burners, laminar flow may exist in narrow premixing ducts before turbulence is introduced. Maintaining laminar flow where desired helps achieve uniform mixing, but excessive laminar regions can reduce turbulence needed for flame stabilization.

Material Creep – time-dependent deformation. Related terms: high-temperature alloy, stress relaxation. At temperatures above $0.5 T_{\text{melt}}$, metals such as stainless steel can experience creep, leading to dimensional changes and potential leakage. High-pressure burners operating at 1200 K require materials with low creep rates, often employing nickel-based superalloys and proper heat treatment.

NO_x Reduction Technology – emission control method. Related terms: SCR, SNCR, staged combustion. Technologies applied to high-pressure burners to meet stringent emission limits. Staged combustion and flue-gas recirculation are primary design approaches; selective catalytic reduction (SCR) may be added downstream for further reduction. Each method adds complexity, cost, and maintenance considerations.

Oxygen Enrichment Ratio – O₂ concentration increase. Related terms: O₂-enriched air, oxy-fuel. Defined as the ratio of enriched oxygen concentration to that of ambient air ($\approx 21\%$). Ratios of 1.2–1.5 are common in high-pressure burners to boost flame temperature while reducing CO₂ volume. Requires sealed systems and careful control to avoid over-temperature conditions.

Pressure Transducer – measurement sensor. Related terms: pressure gauge, strain gauge. Devices that convert pressure into an electrical signal for monitoring and control. High-pressure transducers must withstand the operating range (up to 30 bar) and provide high accuracy ($\pm 0.5\%$). Calibration drift due to temperature fluctuations is a common issue.

Recirculation Ratio – flue-gas reuse proportion. Related terms: FGR ratio, dilution factor. The fraction of exhaust gas returned to the combustion zone. Ratios of 0.1–0.3 are typical for NO_x control in high-pressure burners. Higher ratios increase flame stability but may reduce overall efficiency due to lower oxygen availability.

Safety Interlock – protective control logic. Related terms: shutdown circuit, fail-safe. A system that monitors critical parameters (pressure, temperature, flame presence) and initiates a safe shutdown if limits are exceeded. In high-pressure burners, interlocks are mandatory to prevent catastrophic failure, and they often incorporate redundant sensors and self-diagnostic features.

Swirl Generator – vorticity inducer. Related terms: vanes, tangential inlet. Devices that impart angular momentum to the flow, creating a vortex that enhances mixing and stabilizes the flame. Swirl generators can be integral to the nozzle or separate blade assemblies. Design parameters include vane angle, number of blades, and inlet diameter, all of which affect the swirl number.

Thermal Stress – temperature-induced strain. Related terms: expansion coefficient, fatigue. Differential heating of burner components leads to stress concentrations that can cause cracking or deformation. High-pressure burners experience rapid temperature changes during start-up and shut-down, necessitating careful material selection and gradual ramp rates to mitigate stress.

Transient Response – dynamic system behavior. Related terms: step change, time constant. The time it takes for a burner to adjust to changes in set-point (e.g., fuel flow increase). High-pressure burners often exhibit slower transients due to the inertia of dense gases. Controllers use predictive algorithms to minimize overshoot and maintain stability during load changes.

Ultra-Low NO_x Burner – advanced emission design. Related terms: catalytic burner, staged combustion. Burners engineered to achieve NO_x emissions below 10 ppm at 3 % O₂. They combine multiple stages, precise AFR control, and often employ catalytic surfaces to promote low-temperature oxidation. Cost and complexity are higher, but they are essential for processes with strict environmental regulations.

Vapor-Phase Fuel – gaseous hydrocarbon. Related terms: methane, LPG, natural gas. In high-pressure burners, vapor-phase fuels are preferred for their ease of mixing and predictable combustion characteristics. Liquid fuels require vaporization systems, adding complexity and potential for uneven distribution. Vapor-phase fuels also enable more accurate flow measurement with MFCs.

Water-Cooled Burner – heat extraction method. Related terms: cooling jacket, annular coolant flow. Incorporates channels for water circulation around the burner head to remove heat and protect components. Essential for burners operating above 1500 K. Cooling water must be supplied at sufficient pressure to overcome the high internal pressure of the combustion system.

Zero-Emissions Combustion – ideal combustion goal. Related terms: carbon capture, oxy-fuel. Refers to combustion processes that produce no measurable pollutants (NO_x, CO, unburned hydrocarbons). Achieved through a combination of oxygen enrichment, precise staging, and post-combustion treatment. While theoretically possible, practical implementation in high-pressure burners requires advanced control, high-grade materials, and often integration with carbon capture technologies.
